## Abstract

To elucidate the dynamics of a suite of organochlorine contaminants (PCBs, HCB), PAHs and Hg and verify the potential of these pollutants as reliable fingerprints of sources, an ensemble of marine sediments and organisms (finfish, shellfish species and *Mytilus galloprovincialis*) were analysed from the contaminated Augusta Bay (Southern Italy). The Hg and HCB concentration in the sediments exceeded the EQS of the Directive 2000/60/EU. Similarly,  $\Sigma$ PCB and selected PAHs were above the threshold limit set by regulation. The marine organisms showed Hg concentrations above CE 1881/2006. Contaminants in transplanted mussel evidenced an increased accumulation overtime and different distribution patterns between sampling sites. Analysis of the homolog composition of PCB congeners revealed comparable patterns between sediments and marine organisms and offered the opportunity to define a robust fingerprint for tracing contaminants transfer from the abiotic to the biotic compartments. These results were confirmed by the Fluoranthene/Pyrene, Hg and HCB distribution modes.

**Keywords:** Organochlorines, PAHs, Biota, Sediment, Source fingerprint.

## 1. Introduction

Understanding the transfer of contaminants from marine sediments to biota represents a critical aspect for environmental risk assessment, modelling and specific remediation actions (Gobas and Arnot, 2010). Distribution patterns of pollutants, isotope measurements, compositional analysis and investigation of variable proportions of single congeners of specific organic pollutants were shown as valuable tools for tracing sources of contamination to the trophic chains (e.g., Sahu et al., 2009; Baskaran, 2011; Rodenburg and Leidos, 2017; Habibullah-Al-Mamun et al., 2019; Bonsignore et al., 2020).

42 Although several actions have been taken to reduce or even eliminate input of contaminants in the  
43 environment (UNEP 2001, 2017, 2019), compounds such as Persistent Organic Pollutants (POPs)  
44 and some trace metals, including Hg, are accumulated in different environmental matrices thus  
45 representing a global environmental threat for marine organisms and human health (García-Flor et  
46 al., 2009; Bellas et al., 2011; Sanchez-Avila et al., 2012; Berrojalbiz et al., 2014; Olenycz et al.,  
47 2015; Batang et al., 2016; Jepson et al., 2016; Beiras, 2018). Due to their hydrophobic behaviour in  
48 aquatic ecosystems, most of the pollutants such as e.g. Polychlorinated biphenyls -[PCBs],  
49 Hexachlorobenzene [HCB] and Polycyclic Aromatic Hydrocarbons [PAHs], readily bind to  
50 particles (suspended in seawater and/or into the sediments) and are strongly associated with organic  
51 phase. Once in the sediments they persist for very long time (Minh et al., 2007) with high potential  
52 to be incorporated into the food web via benthic–pelagic coupling (Thomann et al., 1992). As an  
53 example of extremely stable compounds, Hexachlorobenzene (HCB) was produced for industrial  
54 and agricultural applications worldwide (Courtney, 1979; Bailey, 2001; Meijer et al., 2003), and  
55 although its production was stopped before 2000 in most countries, it is still abundant in the  
56 environment due to its long-half life in water and sediments (Barber et al., 2005). PCBs were  
57 produced in the past century, up to the 1970s-1980s, and largely used for different industrial  
58 applications (e.g. as dielectric fluid in electrical transformers and capacitors, active constituent of  
59 pesticides) (ATSDR, 2000; Crinnion, 2011). Among 209 congeners, the Stockholm Convention  
60 reports as mandatory to measure at least six indicator congeners non-dioxin-like (NDL) PCBs 28,  
61 52, 101, 138, 153 and 180 to estimate environmental PCBs contamination (JECFA, 2018), while  
62 ICES (Webster et al., 2013) recommends the measure of 7 PCBs congeners (including also  
63 congener 118) which represent a large percentage of the total congeners measured in environmental  
64 samples and human fluids (EFSA, 2010; IARC, 2016). Likewise, Hg is a trace metal efficiently  
65 transferred and biomagnified along food web reaching high concentrations in the upper trophic  
66 levels and thus representing a risk to human health (e.g., Signa et al., 2017).

67 Finally, PAHs represent another group of chemicals of priority concern which include the largest  
68 known class of carcinogens and chemical mutagens (Keith and Telliard, 1979). PAHs tend to  
69 adsorb rapidly on particles (Neff, 1979; Landrum and Robbins, 1990) and since their solubility  
70 decreases with increasing molecular weight, the bioaccumulation of these chemicals from  
71 sediments to marine organisms is generally higher for those with lower molecular weight (Porte and  
72 Albaigés, 1993; Djomo et al., 1996).

73 Over the last decade, a number of scientific contributions explored the distribution patterns of  
74 classes of contaminants (e.g., PAHs, PCBs, PCDD/Fs, Hg and HCB) to trace transfer dynamic from  
75 the sediments to the biotic compartment, and to characterize sources of variability in contaminant  
76 bioavailability to aquatic biota (e.g. Selck et al., 2012; McLeod et al., 2015).

77 Fish and other key species have been used as bioindicators to investigate the presence and toxic  
78 effects of chemical pollutants (Ueno et al., 2003). It is well-known that biotransformation pathways  
79 significantly modulate absorption, distribution and excretion of organic xenobiotics in fish while  
80 filter feeders, such as bivalve, tend to accumulate these pollutants in their tissues from both water  
81 column and sediments thus providing additional information on the environmental state of pollution  
82 (Regoli et al., 1998; Wiberg et al., 2002; Olenycz et al., 2015; Farrington et al., 2016; Beyer et al.,  
83 2017).

84 However, PCBs congeners distribution in the biota generally remains similar to the un-weathered  
85 PCBs mixtures in the sediments (mainly when those with higher chlorine content are considered),  
86 thus allowing the identification of these sources with a satisfactory degree of confidence. Some  
87 exercises of PCBs fingerprinting in biota have been performed in the Hanford Site in Washington  
88 State (Rodenburg et al., 2015) and Portland Harbor in Oregon (Rodenburg et al., 2019) offering  
89 robust information on the transfer of contaminants from the abiotic to the biotic compartments.

90 In this work, we present an unprecedented dataset of Hg, HCB, PCBs and 16 priority PAHs  
91 measured on surface sediments, mussels, and several species of marine organisms from the highly  
92 contaminated marine area of Augusta Bay (southern Italy). Patterns of PCBs congeners, combined

93 to spatial distribution of PAHs, HCB and Hg in sediments and biota were elaborated to evaluate the  
94 fingerprint association between sediments (sources) and biota, and their opportunity for high-  
95 resolution tracing of priority contaminants sources.

96

## 97 **2. Study area**

98 Augusta Bay is a ~ 25 km<sup>2</sup> area located in the eastern Sicilian coast (Fig. 1) which hosts one of the  
99 most important harbours of the Mediterranean Sea and, since 1950s, one of the largest  
100 petrochemical complexes in Europe, characterized by oil refineries and chlor-alkali plant.  
101 Uncontrolled industrial discharges led to significant contamination of sediments by metals and  
102 organics, mainly Hg, PCBs, PAHs and HCB (ICRAM, 2008; Bellucci et al., 2012; Croudace et al.,  
103 2015), and all the area was included in the National Remediation Plan by the Italian Ministry of  
104 Environment. Several investigations have highlighted a strong contamination of the marine  
105 environment with i) abnormal levels of Hg, PCBs and HCB in sediments (ICRAM, 2005, 2008,  
106 Bellucci et al., 2012; Sprovieri et al., 2011; Orecchio and Polizzotto, 2013), ii) active fluxes of Hg  
107 from the sediment to the water column (Salvagio Manta et al., 2016; Denaro et al., 2020) and iii)  
108 Hg evasion processes to the atmosphere (Sprovieri et al., 2011; Bagnato et al., 2013). Serious  
109 impacts on the ecosystem have been documented by ecotoxicological investigations which revealed  
110 genotoxic damages and high Hg contents, exceeding the regulatory limits for food consumption in  
111 the tissues of fish and mussels (Ausili et al., 2008; ENVIRON, 2008; ICRAM, 2008; Tomasello et  
112 al., 2012; Bonsignore et al., 2013; Signa et al., 2017), thus advising for possible human health  
113 implications due to consumption of seafood from this area (Ausili et al., 2008; Bonsignore et al.,  
114 2013; Di Bella et al., 2020).

115 The role of polluted sediments as the main carrier of Hg to the ecosystem and local fish consumers  
116 has been further revealed through the exploration of Hg isotopes signature in sediments and fish  
117 (Bonsignore et al., 2015).

118

### 119 3. Sampling activity

120

#### 121 3.1 Sediments

122 The sediment sampling, carried out in October 2017 during an oceanographic cruise on board R/V  
123 “Luigi Sanzo”, provided sediment cores from 4 stations (A3, A7, A9, A11) inside the bay, from the  
124 northern to the southern area (Fig. 1), using an oceanic box-corer. Sediment cores were immediately  
125 stored at –20 °C until the analyses.

126

#### 127 3.2 Marine organisms

128 In November 2013, wild mussels (*Mytilus galloprovincialis*) with size range 3.6-6 cm, were  
129 manually collected from industrial wharf and rapidly transported to laboratory for the tissue’s  
130 dissection. In the same period, a total of 62 specimens of finfish (*Sphyraena sphyraena*, *Mullus*  
131 *barbatus*, *Pagellus* spp., *Sparus aurata*, *Serranus cabrilla*, *Diplodus* spp.) were obtained through  
132 local fisherman (Fig. 1).

133 In September 2017, mussels (*Mytilus galloprovincialis*) with size range of 4-6 cm were obtained  
134 from a commercial farm. A pool of individuals (about 2 kg) was used as control (*M.*  
135 *galloprovincialis CTRL*), while other two pools (about 10 kg) were transplanted in the northern (*M.*  
136 *galloprovincialis N*) and the southern (*M. galloprovincialis S*) areas of Augusta Bay, caged in nylon  
137 net bags, secured to a rope and maintained at approximately 3 m water depth. After a period of 5  
138 weeks, a subgroup of mussels was collected from each site (*N1* and *S1*), and an additional sampling  
139 was performed 7 months later (*N2* and *S2*).

140 In October 2017, a total of 96 specimens of finfish (*Sphyraena sphyraena*, *Trigla lucerna*, *Mullus*  
141 *barbatus*, *Pagellus* spp., *Diplodus* spp.) and shellfish (*Parapaeneus kerathurus* and *Sepia* spp.)  
142 were obtained through local fishermen (Fig. 1).

143

### 144 4. Analytical methods

145 *4.1 Samples preparation*

146 In laboratory, the sediment cores were defrosted, extruded and immediately sliced into 1 cm  
147 intervals. The samples were then dried at 35°C and homogenized by an agate mortar. For the goals  
148 of this study only the most superficial levels (between 0-10 cm) were analysed.

149 The total length (mm) and the weight (g) for each organism were measured and muscles and soft  
150 tissues were dissected by stainless steel scissors. Individuals of each species with comparable size  
151 were pooled, homogenized and stored at -80°C (Table 1). The tissues samples were then freeze-  
152 dried and powdered by an agate mortar prior the analyses.

153

154 *4.2 Mercury determination in sediments and marine organisms*

155 The concentration of Hg in organisms and sediments was determined by a direct mercury analyzer  
156 (milestone-DMA-80 atomic absorption spectrophotometer), according to analytical procedures  
157 reported in EPA 7473 method (2007). About 0.050 g of dried tissue and ~0.010 g of dry sediment  
158 were loaded in nickel boats and transferred into the DMA-80 system. The Certified Reference  
159 Materials-TORT-2 Lobster hepatopancreas and (PACS-2 Marine sediment, NRC-CNRC) were used  
160 to assess accuracy (estimated % error =3%) and precision (routinely better than 4%; RSD%, n = 3).

161 About 20% of the total number of samples was duplicated to estimate reproducibility (better than  
162 7%). Acid-cleaned laboratory materials were used in order to minimize contamination risks during  
163 sample preparation and analyses procedures. Analyses were performed at the biogeochemical  
164 laboratory of the Institute of Anthropic impacts and Sustainability in marine environment (IAS-  
165 CNR) of Capo Granitola (Trapani, Italy). Results were expressed as on wet weight basis.

166 Results relative to tissues were converted from dried to wet-weight ( $\mu\text{g g}^{-1}$ ) applying a conversion  
167 factor previously calculated using the following formula:  $C_w = C_d \times (100 - \%H_2O / 100)$  where  $C_d$  and  
168  $C_w$  are the concentration expressed relatively to dry and wet mass respectively.  $\%H_2O$  is the  
169 percentage of humidity (ranging around 80% for almost species) calculated after the freeze-drying  
170 process (Di Bella et al., 2020 and references therein).

171

172 *4.3 PCBs, HCB and PAHs determination in sediments and marine organisms*

173 The sediment and biota samples were freeze dried and homogenized, then an aliquot (about 1 and 2  
174 g of tissues and sediments, respectively) was placed in an ASE 200 steel extraction cell, spiked with  
175 surrogate standards (o2si smart solution ® custom deuterated PAH mix; Wellington Laboratories  
176 Inc PCB mix; CDN Isotope Inc HCB standard solution) for recovery monitoring and extracted by  
177 pressurized fluid extraction using a moderately polar solvent mixture. The resulting extract was  
178 cleaned up according to the matrix (sediment or biota) and the analytes (organochlorines or PAHs)  
179 by a combination of column chromatography on silica (PAH) and florisil (organochlorine)  
180 adsorbents and a shaking of the extract with a NaOH solution (PAH in biota) or with concentrated  
181 sulphuric acid (organochlorine). For the determination of organochlorine compounds in sediment  
182 samples the extract was also shaken with activated copper powder for sulphur removal. The cleaned  
183 up concentrated extract was spiked with injection internal standard and analysed by GC/MS/MS for  
184 organochlorine and GC/MS for PAHs.

185 PAH contents in sediments were compared to values established by the Italian regulation  
186 (Legislative Decree 172/2015). Benzo(a)pyrene and Fluorantene were monitored in biota,  
187 specifically in molluscs as suggested by Legislative Decree 172/2015.

188 Reference materials for sediments (SRM 1941b-NIST, organics in marine sediments) and biota  
189 (NIST 2974a, organics in freeze-dried mussel's tissue - *Mytilus edulis*) were analysed to estimate  
190 the accuracy (recoveries for each analyte of PAHs, PCBs and HCB ranged between 94% and  
191 107%). The reproducibility, estimated on tripled samples, was better than  $\pm 10\%$  and analytical  
192 precision was routinely better than 4% (RSD%, n = 3).

193 For the PCB class of contaminants, we referred to the following notation:  $\Sigma$ PCBs (sum of all the  
194 measured congeners),  $\Sigma$ PCBs<sup>1</sup> (sum of PCB congeners according to Italian Legislative Decree  
195 172/2015 for marine sediments),  $\Sigma$ NDL-PCBs (PCB 28, 52, 101, 153, 138 and 180) and  $\Sigma$ 7PCBs  
196 ( $\Sigma$ 6PCBs + PCB 118).

197

#### 198 *4.4 Statistical analysis*

199 All the statistical analyses and graphics were performed using the statistical software R 3.6.3 (R  
200 Development Core Team, 2020). Box-whisker plots of measured Hg, HCB and PCBs were used to  
201 provide synthetic and direct comparisons for these parameters among the cores. For statistical  
202 analysis, all values below the limit of detection (LOD) were set-up as  $\frac{1}{2}$  LOD.

203 A hierarchical cluster analysis (HCA) with Euclidean distance and Ward's grouping method was  
204 applied to the ratio 'individual PCB congener/ $\Sigma$ PCB' in order to create homogeneous clusters of  
205 samples (sediments, fishes and mussels) based on similarity of PCBs composition. The elbow  
206 method was used to determine the most statistically reliable and representative number of clusters,  
207 minimising the total intra-cluster variation.

208

### 209 **5. Results and Discussion**

210

#### 211 *5.1 Contaminants in sediments*

##### 212 *5.1.1. Mercury*

213 Mercury concentrations measured in the A3, A7, A9 and A11 cores ranged from 3.07 to 12.2  $\mu\text{g g}^{-1}$   
214 (Tab. 2; Tab. S1) widely exceeding (generally more than one order of magnitude) the  
215 Environmental Quality Standard (EQS), defined in accordance with Directive 2000/60/EU as  
216 criteria for the achieving of the Good Chemical and Ecological Status of water bodies, and  
217 established by the Italian regulation (Legislative Decree 172/2015; 0.3  $\text{mg kg}^{-1}$ ). The highest values  
218 ( $\text{mean} \pm 1\sigma = 11.4 \pm 0.57 \mu\text{g g}^{-1}$ ) were found in A9 core collected from the south-western sector of the  
219 bay, in front of the past chlor-alkali plant (Tab. 2; Fig 2a). The lowest concentration ( $\text{mean} \pm 1\sigma =$   
220  $3.64 \pm 0.27 \mu\text{g g}^{-1}$ ) was recorded in the A3 core sampled in the northern area (Tab. 2, Fig. 2a).  
221 Finally, A7 and A11 cores, collected from the central and southern part of the bay, showed  
222 comparable levels of Hg ( $\text{mean} \pm 1\sigma = 6.71 \pm 0.80 \mu\text{g g}^{-1}$  and  $6.54 \pm 1.28 \mu\text{g g}^{-1}$ , respectively).

223

### 224 *5.1.2. Organochlorine compounds (HCB and PCBs) and PAHs*

225 The analysis of organochlorine compounds in sediments showed very high concentrations of HCB  
226 in all the analysed cores, ranging from 1.98 to 330 ng g<sup>-1</sup> (Tab. 2; Tab. S1). The mean values  
227 registered from each core, again considering only the superficial 10 cm of sediments, were  
228 considerably above the EQS for marine sediments (0.4 ng g<sup>-1</sup>), with highest values measured in the  
229 A9 core (mean±1σ = 172 ± 87.6 ng g<sup>-1</sup>) (Tab. 2; Fig. 2b).

230 Also ΣPCBs and Σ7PCB registered higher values in A9 core (41.9 ± 5.60 ng g<sup>-1</sup>; Tab. 2; Tab. S1;  
231 Fig. 2c,d). The ΣPCBs also exceeded EQS value (8 ng g<sup>-1</sup>) for sediments in all cores (Tab. 2).

232 The average concentrations of the individual PAHs were, in some cases, above the EQS indicated in  
233 Tab 1/A of the Legislative Decree 172/2015 Specifically, the Anthracene concentrations (range =  
234 23.4-286 ng g<sup>-1</sup>) were above the EQS (24 ng g<sup>-1</sup>) in all the analyzed samples; most of the A3 levels  
235 showed concentrations of Benzo-a-Pyrene (mean±1σ = 64.7 ± 20.1 ng g<sup>-1</sup>; EQS = 30 ng g<sup>-1</sup>),  
236 Benzo-b-Fluoranthene (mean±1σ = 54.6 ± 20.4 ng g<sup>-1</sup>; EQS = 40 ng g<sup>-1</sup>) and Benzo-k-Fluoranthene  
237 (mean±1σ = 33.6 ± 24.3 ng g<sup>-1</sup>; EQS = 20 ng g<sup>-1</sup>) above the EQS values; furthermore, Indenopyrene  
238 concentrations higher than EQS (70 ng g<sup>-1</sup>) were recorded in the upper part (between 0-6 cm) of the  
239 A3 core (Tab. 2; Tab. S2).

240

### 241 5.2 Contaminants in marine organisms

#### 242 *5.2.1. Mercury*

243 The lowest Hg mean values referred to *Sepia* spp. collected in 2017 (0.21±0.08 µg g<sup>-1</sup>) and *S.*  
244 *aurata* sampled in 2013 (0.32±0.09 µg g<sup>-1</sup>). In most cases, such as *S. sphyraena*, *T. lucerna*, *M.*  
245 *barbatus*, *Diplodus* spp. and *P. kerathurus* (sampled in 2017) and *S. sphyraena*, *S. cabrilla* and  
246 *Diplodus* spp. (sampled in 2013), the Hg levels exceed the threshold limits set by EU regulation for  
247 contaminants in seafood (CE 1881/2006) (Tab. 3). Excluding the effect of age and length, the  
248 contents of Hg found in organisms resulted in most cases higher than values previously measured in

249 the study area. Specifically, the concentrations measured in *Diplodus* spp. ( $1.49 \pm 1.77 \mu\text{g g}^{-1}$  in  
250 2017) and *Pagellus* spp. ( $0.86 \pm 0.44 \mu\text{g g}^{-1}$  in 2017 and  $0.53 \pm 0.12 \mu\text{g g}^{-1}$  in 2013) were higher than  
251 those reported by Bonsignore et al. (2013), Ausili et al. (2003) and ICRAM (2005, 2008), for the  
252 same species (between  $0.56\text{-}0.90 \mu\text{g g}^{-1}$  and  $0.36\text{-}0.41 \mu\text{g g}^{-1}$ , respectively). In red mullet (*M.*  
253 *barbatus*), the concentrations relative to 2013 ( $0.44 \pm 0.20 \mu\text{g g}^{-1}$ ) were in the same range of  
254 measurements ( $0.46\text{-}0.82 \mu\text{g g}^{-1}$ ) of the previous investigations (Bonsignore et al., 2013; ICRAM,  
255 2005, 2008) while those relative to 2017 ( $2.11$  and  $1.71 \mu\text{g g}^{-1}$ ) resulted significantly higher and in  
256 the same range of those reported by ICRAM in 2003 ( $1.49\text{-}1.92 \mu\text{g g}^{-1}$ ). Finally, the Hg  
257 concentration in *T. lucerna* ( $0.66 \mu\text{g g}^{-1}$ ) resulted slightly higher than that reported by ICRAM in  
258 2003 ( $0.57 \mu\text{g g}^{-1}$ ).

259 The bioavailability of Hg in the study area has been confirmed by analyses on both native and  
260 caged mussels with concentrations always higher than the EQS ( $0.02 \mu\text{g g}^{-1}$ ) (Tab.3). Wild  
261 specimens collected in industrial wharf exhibited concentration of approximately about  $0.2 \mu\text{g g}^{-1}$ ,  
262 ~20-fold higher than those measured in control organisms and comparable to those observed by  
263 Ausili et al. (2008) (Tab. 3). Bioaccumulation of Hg demonstrated to be very rapid in caged mussels  
264 showing, after only 5 weeks, comparable values to those of native organisms; after 7 months the  
265 concentrations increased by about 5-fold (Tab. 3). In particular, in the northern area, Hg in mussels  
266 5 weeks after transplant (N1:  $0.02 \pm 0.002 \mu\text{g g}^{-1}$ ) appeared double than in the control sample ( $0.01$   
267  $\mu\text{g g}^{-1}$ ), while after 7 months, the Hg increase was nearly one order of magnitude higher (N2:  
268  $0.12 \pm 0.01 \mu\text{g g}^{-1}$ ) (Tab. 3). Worthy to note, this value is reasonably in agreement with the results  
269 recently reported for mussels in the Augusta Bay ( $0.17 \pm 0.07 \mu\text{g g}^{-1}$ ; Caricato et al., 2019). In the  
270 southern area, when comparing the concentration in pre-deployed mussels, the levels of Hg were  
271 ~23 times higher in those collected after 5 weeks (S1:  $0.23 \pm 0.02 \mu\text{g g}^{-1}$ ) and up to 89 times higher  
272 after 7 months (S2:  $0.89 \mu\text{g g}^{-1}$ ). The latter value exceeds the threshold limits set up by EU  
273 regulation for contaminants in seafood ( $0.5 \mu\text{g g}^{-1}$ ; Reg. CE 1881/2006) and appeared much higher  
274 than those reported for many other Mediterranean sites (range:  $0.01\text{-}0.20 \mu\text{g g}^{-1}$ ; Amodio-Cocchieri

275 et al., 2003; Ipolyi et al., 2004; Licata et al., 2004; Cardellicchio et al., 2010; Kljaković-Gašpić et  
276 al., 2010; Spada et al., 2011, 2012, 2013; Caricato et al., 2019).

277

### 278 5.2.2. HCB, PCBs and PAHs

279 Concentrations of HCB, PCBs and PAHs measured in organisms are reported in Table 3. Values of  
280 HCB were <LOD (0.05 ng g<sup>-1</sup>) in all species of finfish and shellfish sampled in 2017, except for *S.*  
281 *sphyraena* (1.40 ng g<sup>-1</sup>) and *M. barbatus* (0.24 and 0.65 ng g<sup>-1</sup>); on the other hand, in 2013 they  
282 ranged between 0.09 ±0.02 (*Pagellus* spp.) and 1.36±0.31 ng g<sup>-1</sup> (*Mullus* spp.). All the  
283 concentrations are below the EQS of 10 ng g<sup>-1</sup>.

284 HCB together with PCBs are ubiquitous contaminants in Mediterranean marine coastal areas (Solé  
285 et al., 2000). HCB can be stored in sediments and accumulated in benthic organisms. Being a  
286 lipophilic compound, it has a greater affinity for tissues with high lipid content, thus explaining the  
287 low concentrations measured in almost all the muscle samples of fish analysed in this study. Other  
288 authors have reported data related to HCB in fishes, but a direct comparison appears problematic  
289 due to the high variability of investigated organs/tissues (skin, gills or mussels' tissues) and the  
290 different used reference system (wet, dry or lipid weight) (Domingo and Bocio, 2007). Nonetheless,  
291 when comparable, our results are within the range of concentration reported from other studies for  
292 the Mediterranean Sea (Rodríguez-Hernández et al., 2016; Junquè et al., 2018).

293 PCBs were detected in all the analysed species. The mean values of  $\sum$ PCBs ranged from 28.7 ng g<sup>-1</sup>  
294 (*Diplodus* spp.) to 241.7 ng g<sup>-1</sup> (*S. sphyraena*). The  $\sum$ NDL-PCBs showed variable concentrations  
295 among the analysed species, with a mean value above the limit of 75 ng g<sup>-1</sup> (European Commission,  
296 2011) measured in *S. sphyraena* (168 ng g<sup>-1</sup>) and *M. barbatus* (88.2 ng g<sup>-1</sup>) collected in 2017 and  
297 *Mullus* spp. sampled in 2013 (96.2 ng g<sup>-1</sup>). All the analysed species sampled in 2013 and 2017,  
298 exceeded  $\sum$ 7PCBs threshold limit (10 ng g<sup>-1</sup>) with the lowest and highest value measured in *T.*  
299 *lucerna* (19.0 ng g<sup>-1</sup>) and *S. sphyraena* (180.9 ng g<sup>-1</sup>), respectively (Tab. 3); this value represents the

300 limit above which effects on marine organisms might be expected according to the Ecotoxicological  
301 Assessment Criteria (EACs) of the OSPAR Convention (Campillo et al., 2017). A direct  
302 comparison of the  $\Sigma 7$ PCBs with a previous study (Ferrante et al., 2007) on various edible species  
303 sampled in the Gulf of Naples (Southern Tyrrhenian Sea) showed systematically higher  
304 concentrations in samples from Augusta Bay.

305 The highly-chlorinated congeners CB153 and CB138 (hexa-chlorinated) and CB180 (epa-  
306 chlorinated) exhibited the higher abundance in biota (Tab. 3) and dominated the PCB group in all  
307 the analysed samples, thus mirroring results from other studies (Miao et al., 2000; Solé et al., 2000;  
308 Green and Knutzen, 2003; Castro-Jimenez et al., 2008; Storelli et al., 2009; Scarpato et al., 2010;  
309 Xia et al., 2012; Suarez et al., 2013; Herceg-Romanic et al., 2014; Mohebbi- Nozar et al., 2014;  
310 Kampire et al., 2015; Batang et al., 2016). The major occurrence of these congeners is related to the  
311 high degree of chlorination on the aromatic rings which results in a lower degradation rate by  
312 organisms and a potential bioaccumulation (Jönsson et al., 2003; Storelli et al., 2009). Specific  
313 differences in PCBs content could reflect the dissimilar behaviour and feeding patterns, trophic  
314 levels, physiological status of organisms or metabolic detoxification capacity (Ashley et al., 2003)  
315 typical of the studied species. In particular, *S. sphyraena*, which is an active predatory fish,  
316 occupying a high level in the trophic chain (Premolatha and Manojkumar, 1990), showed the  
317 highest concentration of PCBs with respect to other species. Also, the *Mullus* species exhibited  
318 higher values of  $\Sigma$ PCBs most likely related to their ecological features (bottom-feeder) and  
319 consequently greater probability of exposure to PCBs from sediments.

320 PAHs were measured only in organisms sampled in 2017, revealing differences among the analysed  
321 species both as total content and individual PAHs (Tab. 3). Finfish and shellfish showed a major  
322 content of low molecular weight (LMW) PAHs, while high molecular weight (HMW) PAHs were  
323 all <LOD (0.8 ng g<sup>-1</sup>). The  $\Sigma$ PAHs ranged between 9.22 ng g<sup>-1</sup> (*S. sphyraena*) and 22.0 ng g<sup>-1</sup>  
324 (*Sepia* spp.). The Benzo-a-pyrene (BaP), used as reference of PAHs presence in seafood (Reg. EC

325 1881/2006 as amended), was <LOD in all finfish and shellfish except in mussels. The latter exceed  
326 threshold limit of Benzo-a-pyrene established for molluscs (5 ng g<sup>-1</sup>; Legislative Decree 172/2015).  
327 The OCs pollutants in transplanted mussels showed higher values than those measured in the  
328 control samples, suggesting significant bioaccumulation (Tab. 3). HCB detected in transplanted  
329 mussel samples revealed differences between the two sites, with always higher HCB values in  
330 samples from the southern sites over both the sampling periods (S1 and S2), with levels up to 7 time  
331 higher (1.91 and 3.15 ng g<sup>-1</sup>, respectively) than those measured in the northern site (0.44 and 0.41  
332 ng g<sup>-1</sup>) (Tab. 3). Recorded values, compared to those from other Mediterranean areas (Ferrante et  
333 al., 2007), resulted higher and suggested that mussels from Augusta Bay were exposed to high-  
334 levels of this pollutant.

335 The  $\sum$ PCBs in S1 mussels (35.2 ng g<sup>-1</sup>) was >3 times than values measured in N1 organisms  
336 ( $\sum$ PCBs= 11.66 ng g<sup>-1</sup>). A higher content of  $\sum$ PCBs, compared to N2 (27.1 ng g<sup>-1</sup>), was confirmed  
337 in S2 mussels (39.3 ng g<sup>-1</sup>). Furthermore,  $\sum$ 7PCBs resulted above the OSPAR limit in all samples  
338 except in N1 mussels. The analysis of PCB congeners showed that the penta (101, 118), hexa (138-  
339 153) and epta-chlorinated PCBs (180) were generally more abundant than the less chlorinated forms  
340 (28 and 52) (Tab. 3) reflecting previous data reported by Ferrante et al. (2007), Beiras et al. (2012)  
341 and Campillo et al. (2017).

342 Also, PAHs concentrations were higher in transplanted mussels ( $\sum$ PAHs ranged between 34.2 and  
343 76.4 ng g<sup>-1</sup>) than in the control sample ( $\sum$ PAHs= 25.0 ng g<sup>-1</sup>) with B(a)P showed values above the  
344 EQS (5 ng g<sup>-1</sup>) (Tab. 3). In particular, S1 and S2 organisms exhibited a marked increase of B(a)P  
345 (11.3 and 11.02 ng g<sup>-1</sup>, respectively) in relation to the initial value of control samples (4.3 ng g<sup>-1</sup>).  
346 All samples showed values above the limit of 30 ng g<sup>-1</sup> for Fluoranthene (Tab. 3).

347

## 348 **Discussion and conclusive remarks**

349 Recent studies revealed a systematic correlation between PCBs in biota and in nearly un-weathered

350 PCB mixtures in sediments (Rodenburg et al., 2015, 2019). Several investigations (e.g., Wiegel  
351 and Wu, 2000; Bedard et al., 2005; Zanaroli et al., 2015; Praveckova et al., 2016) evidenced that  
352 dehalogenation processes affect PCBs under strictly anaerobic conditions and low redox potential  
353 and thus changing the congener patterns from highly to low chlorinated congeners.

354 The PCBs composition in surface sediments appears dominated by the higher chlorinated penta,  
355 hexa and hepta CBs, accounting for >60% of  $\Sigma$ PCBs in all samples (Fig. 3). As previously  
356 mentioned, differences in  $\Sigma$ PCBs content measured in the various species, primarily depend on a  
357 number of different ecological features (Ashley et al., 2003; Arnot and Gobas, 2006; Martinez-Silva  
358 et al., 2018) and might reflect a non-homogeneous proportion of the various congeners.  
359 Nonetheless, the compositional patterns of the PCB congeners in the studied fishes appear  
360 reasonably comparable (Fig. 3), and their distribution mode in finfish and shellfish maintains a  
361 systematic order of concentration: hexa->penta->hepta->tetra->tri-CBs, contributing for 58%, 24%,  
362 21%, 4.5% and 0.3% (Fig. 3). Particularly, the major contribution of penta and hexa-CBs is in  
363 excellent agreement with data reported for biota by other authors (Naso et al., 2005; Ferrante et al.,  
364 2007; Howell et al., 2008; Pan et al., 2016; Habibullah-Al-Mamun et al., 2019). The mussels  
365 showed a similar profile although with a minor percentage of epta-CBs accounting for 5.1-8.5% of  
366  $\Sigma$ PCBs (Fig. 3).

367 The composition pattern of the 7 PCB congeners (28, 52, 101, 118, 138, 153 and 180) in all samples  
368 was explored by cluster analysis (Fig. 4), using the elbow method to identify the optimal number of  
369 groups primarily driving the high variability in the studied data population. Except for *Diplodus*  
370 spp., all the finfish and shellfish samples appear strictly grouped in the cluster together with  
371 sediment samples from the A9 core, while all the mussel samples and the other sediment samples  
372 (core A3, A7 and A11) grouped in two separate clusters (Fig. 4).

373 The statistically significant relationship between sediments from the A9 core and finfish and  
374 shellfish suggests a first-order, although robust, insight on the intimate link between the abiotic and

375 biotic compartments and reasonably supports in the study area, the use of the PCB congeners as  
376 potential source fingerprint for these contaminants. Indeed, sediments from the A9 core showed  
377 highly comparable percentages of high-chlorinated congeners (CB 153, 138 and 180) whereas  
378 mussels (native and transplanted) and sediments from the A3, A7 and A11 cores evidence different  
379 PCB patterns. Although the period of permanence of the organisms in the area of the A9 core could  
380 not be precisely assessed, our results suggest that this zone would represent a primary  
381 contamination ‘hot spot’ area for Augusta Bay. Differently, the other sediment cores, characterized  
382 by different and relatively lower PCBs concentration, might represent secondary sources of these  
383 contaminants to the biotic compartment.

384 Analogue pieces of evidence, supporting transfer of contaminants from sediment to biota, again  
385 emerge from the analysis of the distribution patterns of specific PAHs, which in finfish and  
386 shellfish are commonly dominated by LMW hydrocarbons, in particular Fluoranthene and Pyrene.  
387 Indeed, these two molecules have a large range of stability and are good indicators of  
388 thermodynamic vs. kinetic processes (Soclo et al., 2000). The Fluoranthene/Pyrene has been  
389 frequently applied to identify and characterize sources of PAHs in the marine environment (Magi et  
390 al., 2002). On the other side, the distribution pattern of PAHs in mussels has been reported to reflect  
391 accumulation of bioavailable fraction from the water column (Baumard et al., 1998) with  
392 preferential accumulation of LMW PAHs (Varanasi and Gmur, 1981; Broman et al., 1990). The  
393 dotchart in figure 5 evidence a significant correlation between biota and sediments, with  
394 comparable Fluoranthene/Pyrene ratios in finfish, shellfish and A9 sediments. Worthy to note, also  
395 Fluoranthene/Pyrene measured in N2, S1 and S2 mussels which seem to mirror a potential impact  
396 from the A9 sediments. This could primarily suggest an effect of that ‘hot-spot’ area in terms of  
397 resuspension and re-distribution of highly contaminated particles on a relatively wider distance  
398 within the study area (see Denaro et al., 2020 for a complete modelling discussion on the dynamic  
399 within Augusta Bay). Thus, if PCBs seem to offer a primary fingerprint to follow sediment-to-biota

400 transfer of contaminants, the combined use of specific PAHs patterns convincingly supports the  
401 hypotheses of dynamic transfer of those organics in the various environmental compartments.  
402 Particularly, a clear ‘hot-spot’ effect of the A9 sediments on the investigated biotic compartment  
403 can be also documented taking into account the Hg and HCB concentration patterns mirroring  
404 coherent higher concentrations in the analysed benthic fish. Conclusively, the ensemble of achieved  
405 results suggests that combined information from a wide spectrum of contaminants provides a  
406 consistent fingerprint to trace their transfer from sediments to biotic compartments and thus  
407 supports specific remediation decisions and sediment mitigation strategies. Despite the statistical  
408 robustness, the obtained results could primarily reflect specific dynamics of local biogeochemistry  
409 and a critical role of local effects on their distribution patterns, mainly at the abiotic and biological  
410 marine interfaces. However, these promising results encourage to the use of PCB congeners and  
411 pattern of pollutants as fingerprint of exposure pathways from marine sediments to biota in other  
412 marine environmental contexts.

413

#### 414 **Acknowledgements**

415 This work is part of the CISAS (MIUR-CNR) project, funded by the Italian Ministry of Education,  
416 University and Research. The authors wish to thank the colleagues involved in the scientific  
417 collaboration among the National Research Council of Italy, Carmelo Buscaino and Gaspare Buffa  
418 for their support in samples collection during the CNR oceanographic surveys and all the laboratory  
419 personnel of IAS-CNR of Capo Granitola.

| A11  | 22.5             | 37°11'0.37"  | 15°12'48.69" | 11               |

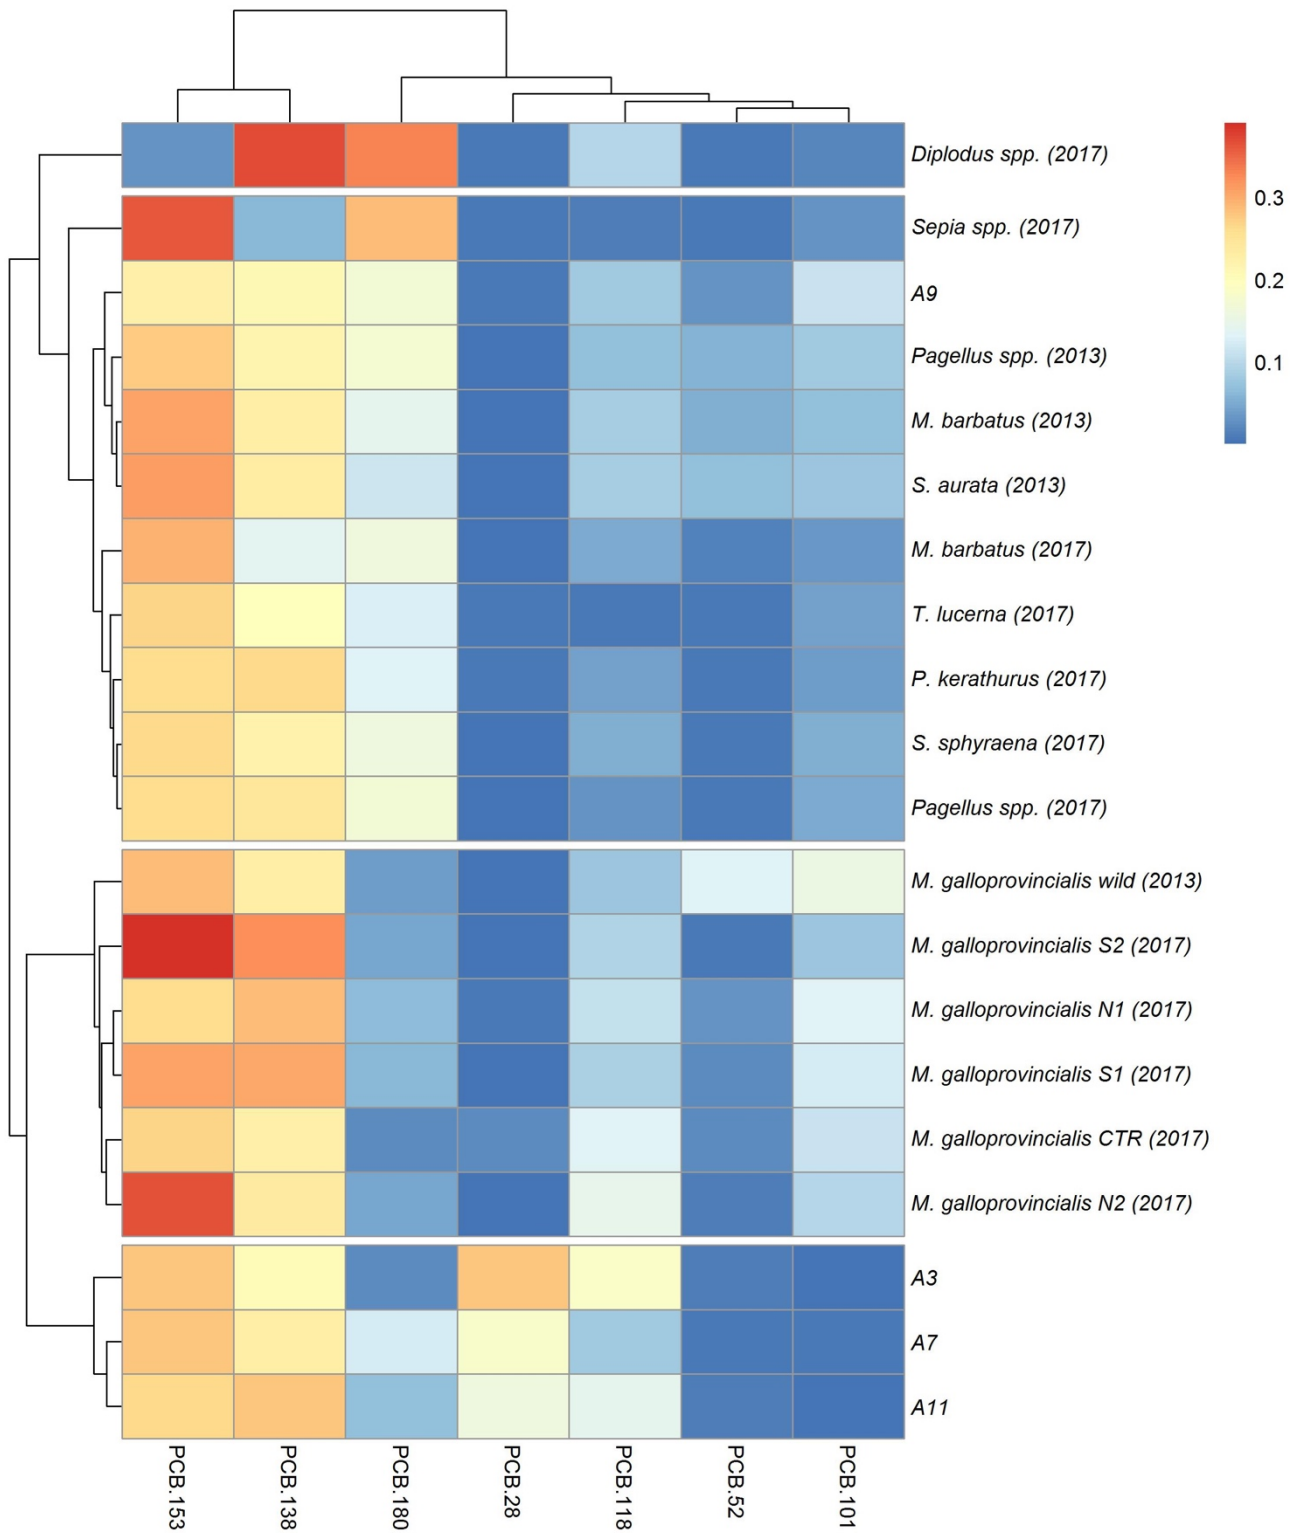

**Figure 1:** Map and details of the sampling in Augusta Bay.

**Figure 2:** Box plot of the concentrations of Hg (a), HCB (b),  $\Sigma$ PCBs (c) and  $\Sigma$ PCBs NDL (d) in sediment cores.

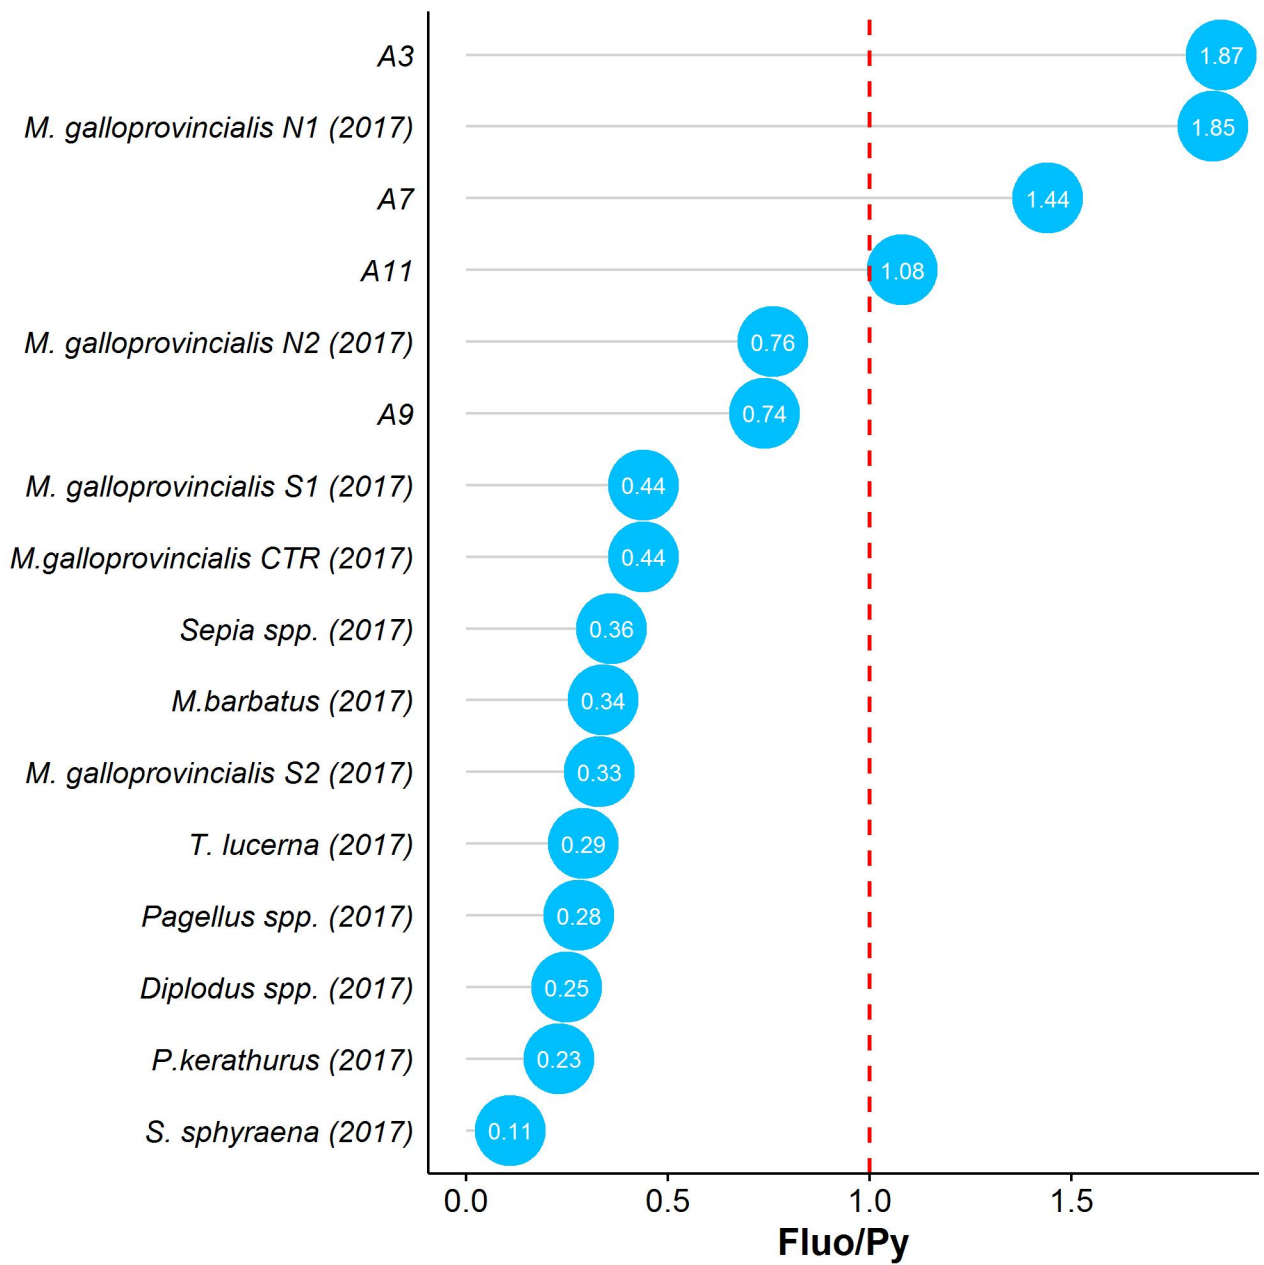

**Figure 3:** Relative contribution of PCB homologs (% composition) in sediments, seafood and mussel samples.

**Figure 4:** Heatmap generated from hierarchical clustering analysis. The dendrograms of sample clustering (on the left) and of congener clustering (on the top) were added. The colour bars inside the graph indicate the different proportion of congeners (X axis) for each sample (Y axis). The rows were splitted based on number of identified clusters.

**Figure 5:** Dotchart of Fluo/Py in sediments and marine organisms
